Supporting Information

**ABSTRACT:** All-solid-state batteries with lithium metal anodes hold great potential for high-energy battery applications. However, forming and maintaining stable solid–solid contact between the lithium anode and solid electrolyte remains a major challenge. One promising solution is the use of a silver–carbon (Ag–C) interlayer, but its chemomechanical properties and impact on interface stabilities need to be comprehensively explored. Here, we examine the function of Ag–C interlayers in addressing interfacial challenges using various cell configurations. Experiments show that the interlayer improves interfacial mechanical contact, leading to a uniform current distribution and suppressing lithium dendrite growth. Furthermore, the interlayer regulates lithium deposition in the presence of Ag particles via improved Li diffusivity. The sheet-type cells with the interlayer achieve a high energy density of 514.3 Wh L<sup>-1</sup> and an average Coulombic efficiency of 99.97% over 500 cycles. This work provides insights into the benefits of using Ag–C interlayers for enhancing the performance of all-solid-state batteries.

**KEYWORDS:** All-solid-state lithium metal batteries, interlayer, silver–carbon composite, sheet-type solid-state cells

All-solid-state lithium batteries hold great promise for electric vehicles (EVs) with long-range capability and improved safety.<sup>1,2</sup> Solid-state electrolytes play an important role in all-solid-state batteries. The solid-state battery design significantly increases the energy density when combined with a lithium metal anode with an extremely high capacity (3860 mAh g<sup>-1</sup>) and the lowest redox potential (−3.04 V vs standard hydrogen potential).<sup>3,4</sup> Among a plethora of promising solid-state electrolytes, sulfide-based solid electrolytes stand out for their remarkable ionic conductivity, low cost, and exceptional processability.<sup>5</sup> The argyrodite-type sulfide electrolytes, such as Li<sub>6</sub>PS<sub>5</sub>Cl (LPSCl), have comparable room-temperature Li-ion conductivities (3 mS cm<sup>-1</sup>) to those of nonaqueous liquid electrolytes.<sup>6</sup> Despite its high ionic conductivity, realizing high-performance all-solid-state lithium metal batteries with sulfide electrolytes remains difficult due to the poor solid–solid contact between the Li anode and solid electrolytes. The contact problem is caused by the inherent surface roughness of lithium metal and electrolyte, which increases interfacial impedance and acts as a precursor for lithium dendritic growth.<sup>7</sup> The formation of voids during lithium stripping on the Li anode deteriorates the metal–electrolyte contact even further.<sup>8</sup>

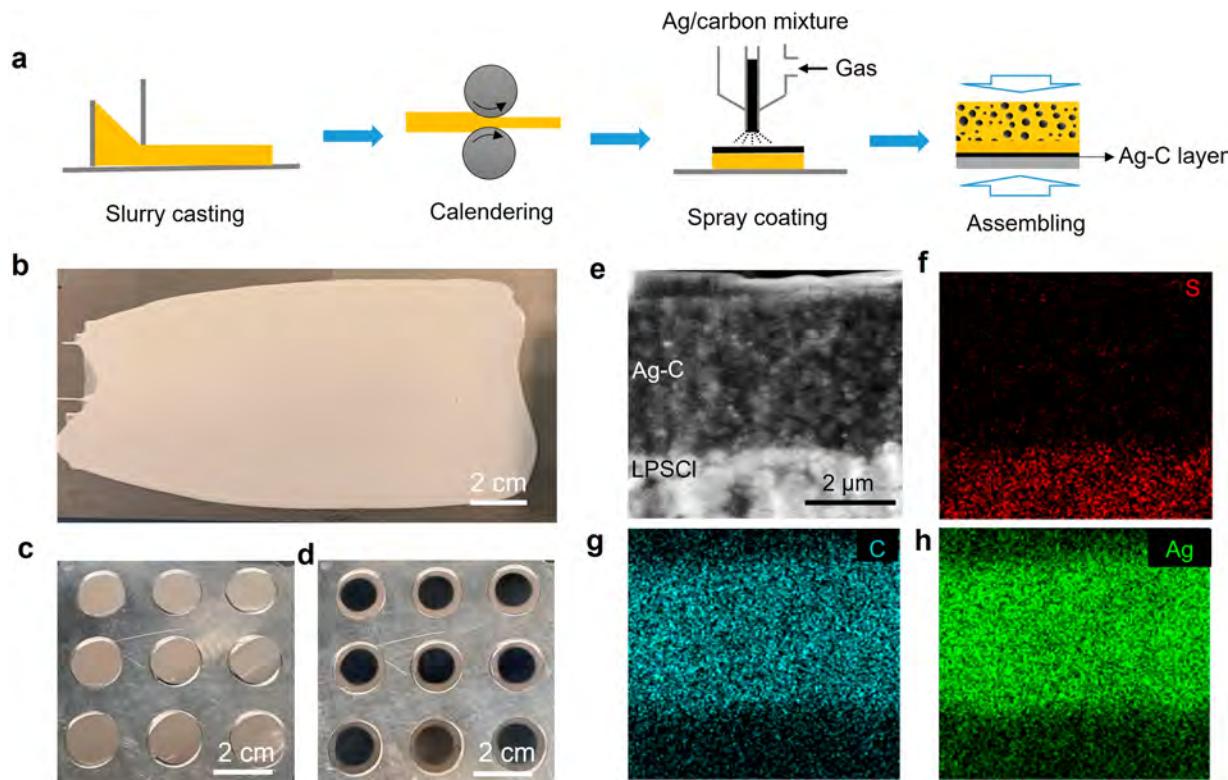

To date, numerous investigations of metal–electrolyte contact in all-solid-state batteries have focused on the development of interfacial engineering strategies. Between the Li anode and solid electrolyte, a mixed ionic–electronic conductor (MIEC) interlayer has been introduced to buffer mechanical strain, promote interfacial contact, alleviate chemical instability, improve stripping/plating homogeneity, and therefore suppress lithium dendrite formation and propagation.<sup>9–12</sup> Lee et al. first reported the screen-printed silver–carbon (Ag–C) composite as an interlayer between the anode current collector and the electrolyte, allowing a high current density (3.4 mA/cm<sup>2</sup>) over 1000 cycles with a consistent Coulombic efficiency greater than 99.8%.<sup>9</sup> Li et al. pointed out that the Ag–C composite possesses a MIEC scaffold nature that regulates Li transport.<sup>10,13</sup> In addition, efforts were made to comprehend the contributions of carbon

black (CB), metal particles, and binders to the Ag–C interlayer. The choice of metal was found to affect lithium growth location, and the binding force between the interlayer and electrolyte determines structural integrity during lithium plating.<sup>11,12</sup> Suzuki et al. studied various metal-added carbon composite anodes for solid-state cells and concluded that Ag outperforms other metals (e.g., Zn, Sn, Al, Ni) in suppressing short circuits.<sup>11</sup> Oh et al. identified the binder effects in the Ag–C composite that allow a strong binding force and an effective buffering of the volume change in the electrode, thus preventing the formation of cracks and enabling a battery with improved mechanical stability and long-term cyclability.<sup>12</sup> Despite the growing interest in exploring the Ag–C interlayer, knowledge of its stable interface mechanisms remains insufficient. This understanding is key to scalable, high-performance solid-state lithium metal batteries.

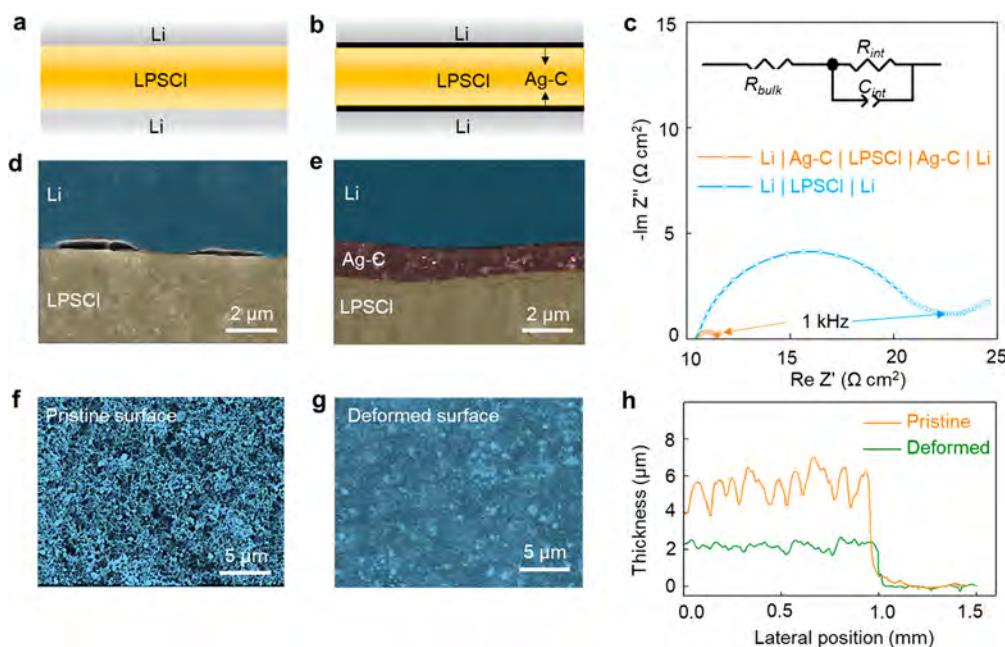

In this study, we report for the use of spray coated Ag–C interlayers for sheet-type all-solid-state lithium metal cells, as well as an investigation of the chemomechanical role of the Ag–C interlayer in addressing Li–electrolyte interfacial challenges. The Ag–C interlayer improves the interfacial contact between Li anode and solid electrolyte, thereby homogenizing the Li<sup>+</sup> flux and suppressing the lithium dendrite growth. This was confirmed by running controlled experiments on a variety of testing cell configurations to examine the Li–electrolyte interface evolution under conditions with and without the interlayer. Furthermore, controlled studies between a pure carbon interlayer and the Ag–C interlayer show that the presence of Ag metal improves Li diffusivity, indicating that Ag metal plays a critical role in regulating lithium deposition in solid-state cells. These discoveries lead to the rational design of Ag–C interlayers, which significantly

improve the electrochemical performance of sheet-type solid-state cells, presenting a promising strategy for the scalable production of high-energy solid-state batteries.

## FABRICATION OF Ag–C|LPSCl BILAYER COMPOSITES

The LPSCl electrolyte attracts much attention due to its superior ionic conductivity and self-passivation interface with the Li anode. In this work, we used a slurry-based method to create a sheet-type solid electrolyte film (Figure 1a).<sup>14</sup> Briefly, a solid electrolyte sheet was fabricated by tape-casting electrolyte slurries onto a silicone-coated poly(ethylene terephthalate) (PET) substrate. LPSCl powder, hydrogenated nitrile butadiene rubber (HNBR), and a 50:50 w/w mixture of anhydrous toluene and isobutyl isobutyrate were mixed to form the slurry. The solid electrolyte sheets were calendered and cut into desired sizes with a hollow punch after drying in vacuum (Figure 1b,c). The solid electrolyte sheet was calendered and densified at 375 MPa. We observed a typical thickness reduction of 50%, resulting in a thickness of 40 μm after calendering.

The Ag–C slurry was then spray coated onto one side of the solid electrolyte sheet via an air-brush technique with argon carrier gas. The Ag–C slurry was prepared by mixing nanosilver particles (60 nm in diameter), carbon black particles, and HNBR in a 5 wt % ratio with the same solvent mixture used for solid electrolyte coating. The total solid content of the slurry was 12 wt %. The Ag–C coated solid electrolyte sheets were removed from the PET substrate and vacuum-dried (Figure 1d). We developed an air-free vessel to transport samples from the glovebox and a Helios SEM/FIB. The bilayer films were examined with cross-sectional SEM

**Figure 2.** Ag–C layer improves the physical contact between Li and LPSCl for pristine cells assembled under a stacking pressure of 5 MPa. (a, b) Cell structures are shown without and with a Ag–C layer, respectively. (c) Impedance spectra reveal an 11-fold reduction in contact resistance with the inclusion of a Ag–C layer. (d) Presence of contact loss without the Ag–C layer is visualized in a cross-sectional SEM image. (e) With a Ag–C interlayer, intimate contact between the layers is revealed without observing contact loss. (f, g) Top-view SEM images of the Ag–C interlayer before and after calendering under 5 MPa. (h) Surface profiles of the Ag–C interlayer before and after calendering.

(Figure 1e). The Ag–C layer has a thickness of about 5 μm. The element distribution of silver, carbon, and sulfur is shown by EDS mapping. We used spray coating as a scalable technique that eliminates the need for free-standing films and lamination. This method has the potential to tackle some of the challenges associated with large-scale production of solid-state batteries (SSBs), particularly scalability and uniformity.<sup>15,16</sup> In comparison to screen printing,<sup>9</sup> the spray coating method demonstrated in this study offers superior uniformity and greater flexibility in controlling the interlayer thickness.<sup>17</sup> Furthermore, with spray coating, waste is significantly reduced, and the starting material is efficiently utilized in fabricating of the active film.<sup>18</sup>

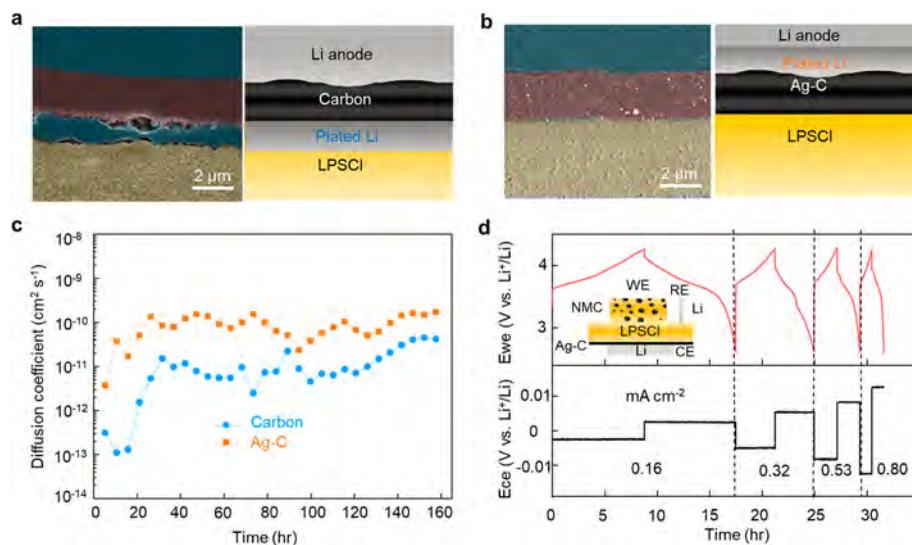

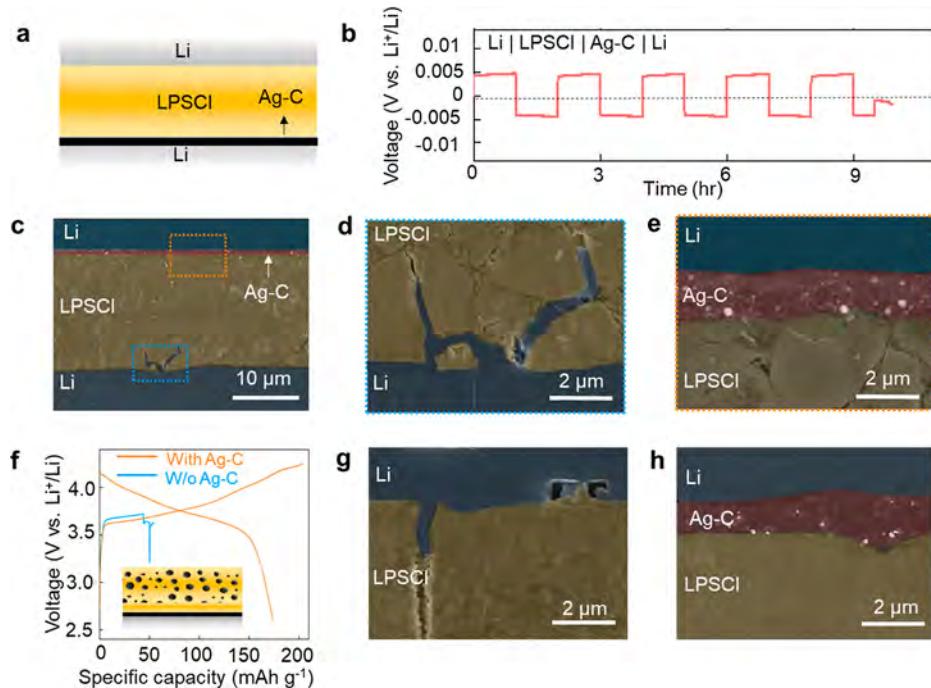

## ■ IMPROVING MECHANICAL CONTACT WITH THE INTERLAYER

During solid-state cell fabrication, interfacing lithium metal with solid electrolyte to form an intimate contact remains a significant challenge. According to Meng et al., stacking pressure is critical in forming excellent contact between the lithium anode and solid electrolyte.<sup>19</sup> The optimum stacking pressure introduces better contact. Inadequate contact may cause high local current density during charge and discharge, resulting in void formation and dendrite growth. The optimum pressure is highly dependent on the electrolyte thickness because a thinner pellet is more susceptible to short circuits due to the significantly shorter path length for the extruded lithium, even at lower stack pressures. It is very likely that Li will infiltrate the thin electrolyte during cell fabrication before intimate contact between the metal and electrolyte can be established (Figure S1).<sup>20</sup> Under low stack pressure, we hypothesize that the excellent deformability of the Ag–C interlayer would contribute to improved Li–electrolyte interfacial contact. Symmetric cells were developed for validation. They were fabricated by pressing two pieces of 30

μm thick lithium metal on opposite sides of an electrolyte sheet with and without Ag–C coating, as shown in Figure 2a,b. The cell was then subjected to 5 MPa pressure.

The interfacial resistance difference of symmetric cells was compared using electrochemical impedance spectra (Figure 2c). In the presence of a Ag–C interlayer,  $R_{\text{int}}$  shinks 11-fold, from 6.59 Ω cm<sup>2</sup> to 0.58 Ω cm<sup>2</sup> (Table S1). We prepared two symmetric cells with exposed cross-sectional interfaces to understand the origin of the impedance reduction. An argon-ion beam cross-section polisher (JEOL IB-19520CCP) was utilized for the exposed interface specimen preparation. The polisher has a much larger cross-sectional polishing area than a standard focused ion beam machining prepared interface. We used an accelerating voltage of 4 kV under cryogenic conditions to minimize heat damage on lithium metal. In addition, to avoid the curtain effect, the sample stage was positioned perpendicular to the ion beam and swung at 30° during milling.

Figure 2d,e shows the cross-sectional SEM images of symmetric Li|LPSCl|Li cells with and without Ag–C interlayers. Figure 2d visualizes the gaps at the Li–LPSCl interface, the size of which is about 3 μm in width and the range of about 0.1–0.3 μm in height. A similar observation was reported by Sun et al.<sup>21</sup> In contrast, with a Ag–C interlayer, we observe intimate contact among Li|Ag–C|LPSCl (Figure 2e). A profilometer (Bruker DektakXT) was used to characterize the interlayer thickness before and after 5 MPa pressure. Figure 2f–h shows the top view and thickness profiles of pristine and deformed samples, which exhibit a 72.2% reduction in roughness and a 59.7% reduction in thickness. In other words, the Ag–C interlayer functions as a mechanical buffer between Li and LPSCl, which have very different mechanical moduli.<sup>22,23</sup>

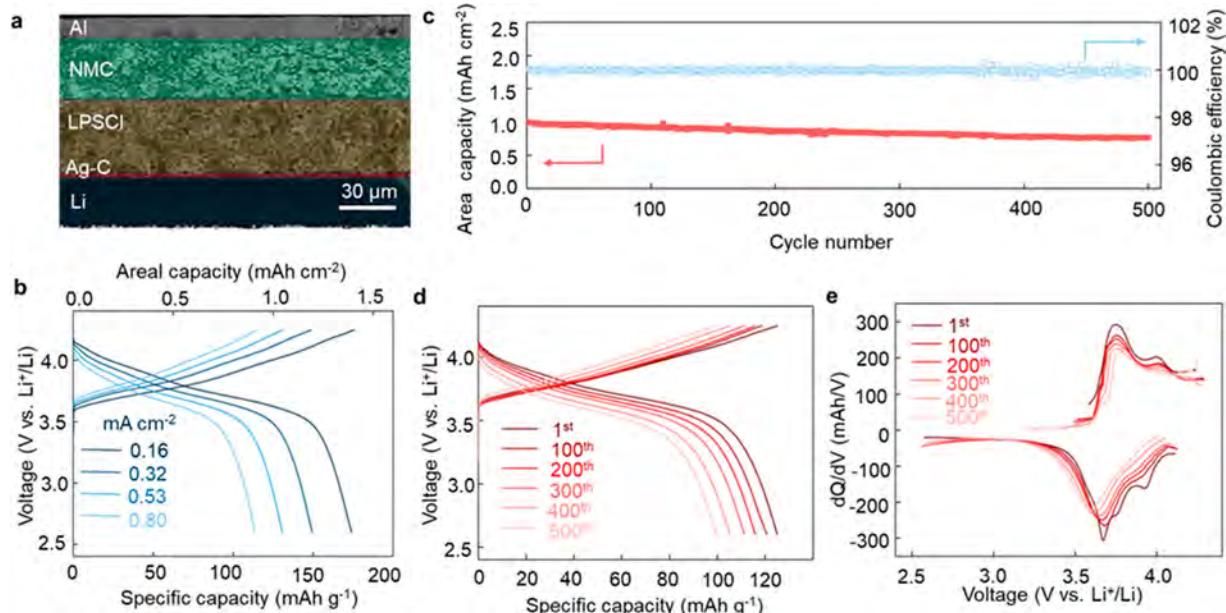

**Figure 4.** Fully lithiated Ag-C interlayer enables lithium plating at the correct location. (a, b) Cross-sectional SEM images and corresponding illustration of full cells after 1st charge. Corresponding galvanostatic voltage profiles are shown in Figure S2. In panel a, Li is plated between LPSCI and the carbon layer, while in panel b, Li is plated between Ag-C and Li. (c) Comparison of the diffusion coefficients of various lithiation states of the carbon and Ag-C interlayers. Corresponding GITT voltage profiles are shown in Figure S3. (d) A three-electrode cell was used to separate the overpotential contribution from the cathode and anode at various rates from 0.1 C ( $0.16 \text{ mA cm}^{-2}$ ) to 0.5 C ( $0.8 \text{ mA cm}^{-2}$ ). The schematic setup of the three-electrode configuration is shown in Figure S4.

## ■ UNIFORM CURRENT DISTRIBUTION BETWEEN THE Li ANODE AND SOLID ELECTROLYTE

The nonuniform current distribution between Li metal and solid electrolyte interfaces leads to penetration of lithium dendrites into solid electrolytes.<sup>7</sup> To that end, we investigate the effects of the interlayer on lithium dendrite challenges. The Ag-C interlayer is expected to stabilize the interface during

cycling by homogenizing the current density. We fabricated a cell with asymmetric interfaces  $\text{Li}|\text{Ag-C}|\text{LPSCI}||\text{Li}$  (Figure 3a) and galvanostatically cycled it until it failed. This allowed us to compare its effectiveness in preventing Li metal dendrite formation, as well as identify the location of cell failure and the effect of the interlayer. Figure 3b shows the voltage profile of the cell while cycling at a current density of  $0.16 \text{ mA cm}^{-2}$ . In the fifth cycle, the cell short-circuited. Post-mortem analysis

**Figure 5.** Sheet-type all-solid-state lithium metal cell performance. (a) Cross-sectional SEM image of a sheet-type all-solid-state lithium metal battery with an Al|NMC|LPSCl|Ag—Cl|Li device structure. (b) Rate performance of the cell at various rates from 0.1 to 0.5 C (where 1C is equal to  $1.6 \text{ mA cm}^{-2}$ ). (c) Galvanostatic cycle performance of the cell at C/3 rate. (d, e) Voltage profile and differential capacity ( $dQ/dV$ ) curves for the first, 100th, 200th, 300th, 400th, and 500th cycles, respectively.

(Figure 3c) revealed that the cycled interfaces with and without a Ag—C interlayer differ dramatically. We observed lithium dendrite penetration into the electrolyte layer on one side where there was no Ag—C interlayer. Bruce et al. also observed similar findings with microcomputed tomography (micro-CT).<sup>8</sup> Nonuniform lithium plating generates highly local mechanical stress in the absence of a Ag—C interlayer, causing the electrolyte to crack and Li dendrite penetration.<sup>24</sup> On the other hand, we observed uniform lithium plating and stripping where the Ag—C interlayer was introduced (Figure 3e), and the interlayer remained dense without cracking. It is critical to maintain the structural integrity of the interlayer as the volume of the Li anode changes during plating and stripping.<sup>12</sup>

A symmetric cell, on the other hand, is not the same as a full cell. As in a symmetric cell, the cathode side of the full cell cannot compensate for the expansion and contraction of electrodes caused by lithium metal plating and stripping during cell cycling. The volume change in full lithium metal cells is unavoidable.<sup>25</sup> To that end, we studied the impact of the Ag—C interlayer in full cells using NMC single crystal cathodes. The cathode composite sheet was fabricated using a tape-casting process and lithium–nickel–manganese–cobalt-oxide (NMC) as the cathode active material (CAM). The full cell (NMC|LPSCl|Ag—Cl|Li) was completed by individually pressing the cathode sheet and the Ag—Cl|LPSCl sheet separately at 375 MPa, then co-pressing them at 375 MPa to improve adhesion between the two layers. Finally, a thin lithium metal anode was pressed against NMC|LPSCl|Ag—C under a stacking pressure of 5 MPa. As shown in Figure 3f, the operation of the NMC|LPSCl|Ag—Cl|Li cell was stable. The full cell without the interlayer, on the other hand, failed during the first charging to 3.7 V with a capacity of only  $41 \text{ mAh g}^{-1}$ . An abnormal voltage profile indicates the presence of lithium dendrites. A similar observation of SEM imaging (Figure 3g,h)

in full cells supports the role of the interlayer in suppressing lithium dendrites by resulting in a uniform current distribution.

## THE ROLE OF Ag IN THE INTERLAYER IN DETERMINING Li PLATING LOCATION

The lithium plating location in a solid-state cell has been reported to be impacted by the metal particles added to the interlayer.<sup>11</sup> To better understand the role of Ag metal in the interlayer, we compare two types of interlayers (Ag—C vs C only) in full-cell operation. The voltage profiles (Figure S2) show only a minor difference, but the post-mortem SEM images show a significant difference in the location of plated lithium, as shown in Figure 4a,b. Lithium plating occurred between the electrolyte and the interlayer in the case of the pure carbon layer. When Ag is present in the interlayer, however, lithium is plated in the desired location between the interlayer and the pristine Li anode. Despite the fact that the amorphous carbon layer provides  $\text{Li}^+$  transport channels, the presence of Ag in the interlayer may facilitate Li transport.<sup>26</sup> Both interlayers made of Ag—C and carbon can operate at lower current densities as long as the Li flux from the electrolyte is less than the Li transport capability of the interlayers. Based on our fabrication conditions (e.g., carbon type and binder content), however, only Ag—C shows decent performance at higher current densities ( $0.16\text{--}0.8 \text{ mA cm}^{-2}$ ) due to its superior Li diffusivity. Conversely, inadequate Li transport in the carbon interlayer results in Li accumulation and growth at the interlayer–solid electrolyte interface. Further adjustments to the physicochemical properties of the carbon layer may enhance its high-current handling capability.

We hypothesize that the presence of Ag metal alters the interlayer diffusivity, thereby regulating the location of Li plating. The galvanostatic intermittent titration technique (GITT) was used to study the lithiation process in two asymmetric cells, carbon|LPSCl|Li and Ag—Cl|LPSCl|Li. Figure S3 shows the GITT results of amorphous carbon and Ag—C

interlayers at various lithiated states. The Ag–C interlayer exhibited a lower overpotential than the carbon interlayer, resulting in greater diffusivity of the Ag–C interlayer. Figure 4c summarizes the evolution of the lithium diffusion coefficient in these two types of interlayers. At the 160th hour of lithiation, the Ag–C interlayer has a 4-fold higher diffusivity than that of the carbon-only interlayer ( $1.71 \times 10^{-10}$  vs  $4.21 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$ ). When the interlayer has a high lithium diffusivity, the reduced Li atoms at the interlayer–electrolyte interface will be quickly transported toward the Li–interlayer interface and plated there because there is no nucleation barrier for Li plating on the Li surface. In contrast, at low lithium diffusivity, reduced Li atoms will plate at the interlayer–electrolyte interface, despite the fact that a nucleation barrier for lithium plating exists.

A three-electrode cell configuration was developed to monitor the potential of the Li anode during cell operation, revealing the interlayer's ability to regulate Li diffusivity (Figure S4). Figure 4d shows the *in situ* Li anode potential change monitored with a Li reference electrode (RE) at various cycling rates. The fact that the Li anode potential remains flat during each cycle's stripping shows that no increasing polarization is observed during stripping, even at high rates.<sup>8</sup> The fact that the Li anode potential remains less than 10 mV at 0.8 mA cm<sup>-2</sup> indicates the interlayer maintains a high diffusivity. Future research will provide a quantitative description of lithium plating regulation using a Ag–C interlayer.

## SHEET-TYPE ALL-SOLID FULL CELL PERFORMANCE

With the Ag–C interlayer, the rate performance and cycling stability of the sheet-type full-cell were greatly improved. Figure 5a shows the cross-sectional image of a sheet-type full-cell setup. The overall thickness of the cell is around 100 μm. Figure 5b shows the voltage profiles under a stacking pressure of 5 MPa at 60 °C. The cell cycled galvanostatically between 2.6 and 4.25 V. After 0.1 C, the sheet-type cell yields discharge capacities of 174.02 mAh g<sup>-1</sup>, translating to a specific energy of 250.6 Wh kg<sup>-1</sup> and an energy density of 514.3 Wh L<sup>-1</sup>, which is greater than the majority of solid electrolyte-based Li metal batteries.<sup>27</sup> The cell shows specific capacities of 174.0, 149.4, 130.5, and 113.4 mAh g<sup>-1</sup>, at 0.1, 0.2, 0.33, and 0.5C (1C = 200 mA g<sup>-1</sup>). The areal capacity is 1.39 mAh cm<sup>-2</sup> at 0.1C. Figure 5c,d plots a capacity retention of 80.2% for 500 cycles. The average Coulombic efficiency (CE) is 99.97%. Such a high CE is attributed to the Ag–C interlayer. Figure 5e shows the dQ/dV plot of the first, 100th, 200th, 300th, 400th, and 500th cycles. The reduction peaks gradually shift to lower potential while the oxidation peaks shift to higher potential, indicating that an increase of impedance is the main reason for the capacity decay. This is in contrast to liquid electrolyte lithium cells where the two major mechanisms of dead lithium and electrolyte drying are absent in all solid state cells.<sup>28</sup>

In conclusion, the role of the Ag–C interlayer in the solid-state cell was investigated. The Ag–C interlayer greatly improves the physical contact of the Li–electrolyte interface, which helps to homogenize the current density of the interface. Furthermore, we show how Ag metal facilitates Li transport through the interlayer. The lithiated Ag nanoparticles in the Ag–C have a high Li diffusivity, allowing lithium deposition at the desired Li–electrolyte interface. The sheet-type solid-state cell with the Ag–C interlayer exhibited a superior specific

energy of 250.6 Wh kg<sup>-1</sup> and an energy density of 514.3 Wh L<sup>-1</sup>. The cell also demonstrated excellent cycling stability, with an average CE of over 99.97% for 500 cycles. Understanding the function of the Ag–C interlayer enables the use of a lithium metal anode in sheet-type solid-state batteries, paving the way for the commercialization of high-energy-density solid-state batteries.
